Abstract

Background: Sleep-disordered breathing (SDB) induces nighttime disturbance of arterial gases, such as carbon dioxide. However, it is still unclear whether nighttime SDB-related gas abnormality is related to respiratory dysregulation in daytime. Therefore, we examined the relationship between the arterial partial pressure of carbon dioxide (PaCO₂) at nighttime and the respiratory response to exercise in daytime.

Methods: Eighteen men (age, mean ± SD: 55 ± 11 years) with heart disease underwent multichannel respiratory monitoring through the night with transdermal measurement of PaCO₂ (PtCO₂) reflecting PaCO₂ and a cardiopulmonary exercise test in daytime. The ventilatory equivalent (VE)/carbon dioxide production (VCO₂) slope as an index of ventilatory response to exercise and peak oxygen consumption (VO₂) were obtained with a cardiopulmonary exercise test.

Results: Of the 18 patients, 10 patients had obstructive SDB, 5 had central SDB, and 3 patients did not have SDB. The mean apnea-hypopnea index was 21 ± 17. Minimum nighttime saturation of O₂ was positively correlated with peak VO₂ but not with VE/VCO₂. Nighttime PtCO₂ was not correlated with peak VO₂ but was negatively correlated with the VE/VCO₂ slope of the daytime cardiopulmonary exercise test (r=−0.53).

Conclusion: Nighttime lowering of PaCO₂ in SDB is related to an abnormal ventilatory response to exercise testing in the daytime. This finding suggests that nighttime hyperventilation in SDB alters both nighttime and daytime pathophysiological conditions in patients with heart disease.

Key words: sleep apnea, hypocapnia, ventilatory response, heart disease
Introduction

In patients with both obstructive and control sleep-disordered breathing (SDB), which includes symptomatic and asymptomatic sleep apneas, and those with central SDB, abnormal arterial partial pressure of carbon dioxide (PaCO₂), including hypcapnia and hypercapnia, frequently develops at night through disturbed ventilatory regulation during sleep⁷. Additionally, patients with heart disease often have an enhanced ventilatory response to exercise in the daytime. These 2 phenomena have common features, such as frequent occurrence and poor prognosis, among patients with heart disease. The relationship between these 2 ventilatory abnormalities, however, has not been sufficiently examined.

In previous studies, daytime hypcapnia and hyperventilation during exercise were observed in patients with heart failure and central SDB, and nighttime hypercapnia and a hyperventilatory response to exercise were observed in patients with obstructive SDB⁷⁸. In these studies, however, the nighttime PaCO₂ was not continuously examined. Furthermore, patients with obstructive SDB and those with central SDB have been separately examined, although the overlap between central and obstructive SDBs has recently attracted attention⁷. Therefore, in the present study we examined nighttime hyperventilation using continuous transdermal measurement of PaCO₂ (PtcCO₂) and daytime respiratory disturbance by means of cardiopulmonary exercise testing in patients with heart disease. Then, we evaluated the relationship between PtcCO₂ in the nighttime and the respiratory response to exercise in the daytime.

Materials and Methods

Study Population

The study population consisted of 18 men (age, mean ± SD; 55 ± 11 years) with stable heart disease including 14 with old myocardial infarctions, 2 with dilated cardiomyopathy, 1 with hypertrophic cardiomyopathy, and 1 with hypertensive heart disease. All subjects underwent multichannel respiratory monitoring with recording of PtcCO₂ in the nighttime and cardiopulmonary exercise testing in the daytime. Patients were excluded if they had exercise-induced ischemia, exercise-induced serious arrhythmia, decompensated heart failure, respiratory disease, arteriosclerosis obliterans, or peripheral edema. Furthermore, patients were excluded if they had had a myocardial infarction within 10 days before the study or were older than 70 years or both. Subjects were eligible for this study if exercise was limited only by symptoms of leg fatigue or dyspnea but not by angina, syncope, or claudication. All aspects of the study were carefully explained to the study subjects before informed consent for participation was obtained.

Assessment of SDB and PtcCO₂

All subjects underwent an overnight sleep study with a computerized sleep apnea diagnosis set (Morphus R. Compumedics Ltd, Victoria, Australia) to evaluate SDB. Oronasal signals detected with a thermistor were used as the respiratory sensors, and thoracic and abdominal effort was measured with 2 belt sensors. Percutaneous oxygen saturation (SpO₂) was recorded with digital pulse oximetry (sampling frequency, 1 Hz). Detection of respiratory events and oximetry analysis were performed manually. Apnea was defined as a cessation of airflow for at least 10 seconds, and hypopnea was defined as a reduction in airflow by more than 50% compared with that at baseline for more than 10 seconds, which was accompanied by at least a 3% decrease in the SpO₂. The apnea-hypopnea index (AHI) was defined as the number of episodes per hour of apnea or hypopnea. An AHI ≥5 times/hr was considered to indicate SDB. An episode of obstructive SDB was defined as the cessation of airflow in the presence of thoracic and abdominal wall motion. An episode of central SDB was defined as the cessation of both airflow and thoracic and abdominal wall motion.

The PtcCO₂ was noninvasively and continually measured with a transdermal monitor (9900MKII, Kohken Medical Co. Ltd, Tokyo, Japan). The PtcCO₂ as measured with this method has been reported to be closely correlated with the actual PaCO₂ in
arterial blood samples. To measure the PtcCO₂, the sensor was placed on the inside of the upper arm through a glass electrode. This sensor is kept heated during the test to maintain a sensor temperature of 42°C because of arterIALIZATION of the capillary network at the measurement site. In the present study, we evaluated the minimum SpO₂ and minimum PtcCO₂ during a single night.

**Cardiopulmonary Exercise Test**

All subjects underwent a symptom-limited cardiopulmonary exercise test.

Cardiopulmonary exercise testing was performed with a cycle ergometer (StrengthErgo 240, Mitsubishi Electric Engineering Co., Ltd., Tokyo, Japan) with the subject in the sitting position. After a 4-minute rest period, exercise began with a 4-minute warm-up at 10 or 20 W and 60 revolutions per minute, after which the intensity was increased incrementally by 1 or 2 W every 6 seconds according to the ramp protocol. Heart rate (HR) and 12-lead electrocardiogram were monitored continuously (ML-5000, Fukuda Denshi, Tokyo, Japan). During testing, blood pressure was measured every minute with an automatic indirect cuff manometer (STBD-780B, Nihon Collin Co., Ltd., Aichi, Japan). During testing, blood pressure was measured with an automatic indirect cuff manometer (STBD-780B, Nihon Collin Co., Ltd., Aichi, Japan). Exercise was stopped upon symptoms of exhaustion. During exercise no patient experienced angina, syncope, ischemic ST segment changes, or serious arrhythmia. Oxygen consumption (VO₂), carbon dioxide production (VCO₂), and the ventilatory equivalent (VE) were measured with a breath-by-breath gas analyzer (AE-300, Minato Medical Science, Osaka, Japan), and then we determined the anaerobic threshold (AT) with the V-slope method, peak VO₂, and the VE/VCO₂ slope as an index of ventilatory response to exercise.

**Statistical Analysis**

We examined the relationships between PtcCO₂ during sleep and cardiopulmonary exercise test variables, such as the VE/VCO₂ slope. All values are expressed as the mean ± standard deviation (SD). Variables were compared between groups by means of the unpaired Student’s t-test and chi-square analysis. Correlations were assessed with the Pearson least-squares correlation test, and results are presented as coefficients of correlation. Differences were considered statistically significant at p-values of less than 0.05.

**Results**

Among the 18 patients with stable heart disease, 10 patients had obstructive SDB, 5 patients had central SDB, and 3 patients had an AHI of less than 5. The mean AHI was 21 ± 17.

To clarify whether the nighttime PtcCO₂ abnormality due to SDB affects the clinical background, the 22 patients were classified into 2 groups according to the minimum PtcCO₂: 8 patients had a low minimum PtcCO₂ (minimum PtcCO₂ <37 mmHg) and 10 patients had a normal minimum PtcCO₂ (minimum PtcCO₂ ≥37 mmHg). There were no significant differences in clinical characteristics, such as age, body-mass index, and left ventricular ejection fraction, between the low PtcCO₂ group and the normal PtcCO₂ group (Table 1). Concerning the sleep study, the AHI and the type of SDB had no significant difference between the low PtcCO₂ and

CPEX, cardiopulmonary exercise test; Minimum PtcCO₂, minimum partial pressure of carbon dioxide using the transdermal method during night sleep

![Graphs](https://via.placeholder.com/500)

Fig. 1 Relationship between min SpO₂ and CPEX parameters
Although min SpO₂ was positively correlated with peak VO₂, min SpO₂ had no relationship with VE/VCO₂.

Min SpO₂, minimum saturation of oxygen using transdermal method during night sleep; CPEX, cardiopulmonary exercise test; Peak VO₂, peak oxygen uptake during CPEX; VE/VCO₂, ratio of ventilation to carbon dioxide output during CPEX.

normal PtcCO₂ groups (Table 2). On cardiopulmonary exercise testing there was no difference in exercise load, including watt and peak heart rate, between the low PtcCO₂ and normal PtcCO₂ groups (Table 3).

The nighttime minimum SpO₂ was positively correlated with peak VO₂ but was not correlated with the VE/VCO₂ slope (Fig. 1). The nighttime minimum PtcCO₂ was not correlated with peak VO₂ (r=0.100, not significant) but was negatively correlated with the VE/VCO₂ slope on daytime cardiopulmonary exercise testing (r=−0.530, p<0.05) (Fig. 2).

Discussion

The present study examined the relationship between abnormal PtcCO₂ during nighttime sleep and ventilatory regulation during daytime cardiopulmonary exercise testing in patients with heart disease. We found that nighttime hypocapnia in patients with SDB was related to daytime
hyperventilation during exercise testing regardless of whether the patient had obstructive or central SDB. This finding may indicate that nighttime hyperventilation with SDB, which is thought to be influenced by hyperchemosensitivity, leads to an enhanced daytime ventilatory response to exercise.

Previous studies have documented nighttime hyperventilation in patients with obstructive SDB, daytime hyperventilation in patients with central SDB, and exercise hyperventilation in patients with either type of SDB. However, these previous studies did not sufficiently clarify the relationship between disturbed nighttime respiratory regulation with SDB and daytime abnormal ventilatory control. Problems included the methods of classifying SDB and measuring PaCO2 at a single time point. Although the AHI is usually determined in studies of SDB, the AHI can indicate only the frequency of apnea and hypopnea events but not actual ventilatory efficacy, such as the minute volume of ventilation. Therefore, we should mention the limitation of AHI. Additionally, the PaCO2 during nighttime is thought to undergo time-dependent changes and should be measured repeatedly. We thought that nighttime minimum PtcCO2 has clinical significance because it reflects actual ventilatory efficacy under pathophysiological conditions. Another problem concerns the disregard of overlap between obstructive and central SDBs. Recent reports have revealed that a part of SDB has a serial feature, which is named “complex sleep apnea”, from obstructive SBD to central SBD. This continuity from obstructive SBD to central SBD is thought to be induced mainly by chemoreflex hypersensitivity.

To solve these problems, therefore, the present study classified SDB of the basis of PtcCO2 and examined the total population, including patients with obstructive or central SDB.

In the present study, we found that SDB with hyperventilation leads to an enhanced daytime ventilatory response to exercise in both patients with obstructive SDB and patients with central SDB. Our first finding was that nighttime hyperventilation develops in patients with central SDB and patients with obstructive SDB. Hyperventilation, even in patients with obstructive SDB, was negatively correlated with AHI, although the patients with a low AHI tended to have hyperventilation. Consistent with this worsened hyperventilation, severe obstructive SDB is thought to have renewed character, such as enhanced chemosensitivity, and results in ventilatory overshoot after an obstructive episode. Our second finding was that nighttime hyperventilation in both patients with obstructive SDB and patients with central SDB was related to daytime hyperventilation during exercise testing. Chemoreflex hypersensitivity in both central SDB and severe obstructive SDB has been suggested to

Fig. 2 Relationship between min PtcCO2 and CPEX parameters
Although min PtcCO2 was not correlated with peak VO2, min PtcCO2 was negatively correlated with VE/VCO2.

induce both nighttime hypcapnia and daytime hyperventilation\textsuperscript{[14]}. In patients with heart disease, both hypcapnia and the enhanced ventilatory response to exercise have been reported to be prognostic factors. Previous studies have suggested that hypcapnia has a harmful effect on the cardiovascular system through disturbed myocardial oxygenation, cardiac arrhythmia, vasoconstriction, and enhanced platelet aggregation\textsuperscript{[15]–[17]}. Furthermore, previous studies of central SDB have indicated that hypcapnia is related to the development of ventricular arrhythmia\textsuperscript{[18,19]}. Concerning hyperventilation during exercise, an increased VE/\textit{V}CO\textsubscript{2} slope indicates a poor prognosis in patients with heart disease\textsuperscript{20}. Therefore, we can speculate that a common mechanism between the nighttime hypcapnia and exercise hyperventilation exists in patients with heart disease.

One limitation of the present study concerns measurement of PaCO\textsubscript{2}. We used PtcCO\textsubscript{2} as a variable reflecting PaCO\textsubscript{2} but this is not a direct measurement. Previous studies that have compared PaCO\textsubscript{2} and PtcCO\textsubscript{2} have shown a strong correlation\textsuperscript{[8–10]}. Although we believe that this noninvasive and successive method is precise, we thought that it should be confirmed by a more direct technique. Another limitation is that subanalysis of central and obstructive SDBs is impossible because of the small study population. Therefore, we believe the present results do not fully indicate each feature of SDBs. In the future, we should perform further studies and confirm both the similarities and differences of ventilation abnormalities between central and obstructive SDBs.

This is, to our knowledge, the first study to show the continuing ventilation abnormalities through both central and obstructive mechanisms in patients with heart disease and SDB. Our results suggest that both types of SDB may worsen the pathophysiological condition of patients with heart disease. Therefore, we conclude that respiratory disturbances throughout the day should be considered in patients with heart disease obstructive SDB or central SDB or both.
